Abstract

The research demonstrates a novel three-dimensional finite element analysis to analyze biomechanical changes in a femur with implant. The method uses principal stress projections to determine trabecular trajectories in the femur. Visual comparisons of the projections of the femurs show areas of cortical and cancellous changes due to changes in tensile and compressive stresses, revealing areas of stress shielding. The method also includes a bone remodeling algorithm to simulate bone adaptation. In the experiment, a patient-specific femur model with inhomogeneous material properties was created from CT scans. Models of femurs with implants varying in type and size were also created. Maximum load during walking was simulated with realistic muscle forces, and stress projections of the femur model were compared to trabecular trajectories of a real femur for validation. Bone remodeling was also simulated to investigate changes in projections over time. High correlation was found between the principal stress projections of the computational model and trabecular trajectories of a real femur. Changes in projections were evident for implant models, suggesting stress shielding and bone remodeling. The analysis provides an effective method for planning implants that are ideal for patients and for designing future implants that preserves the biomechanics of the femur to maintain its physiology.

Keywords

Biomechanics, Finite element analysis, Total hip arthroplasty, Bone remodeling

Introduction

Total hip arthroplasty (THA) is a type of joint replacement surgery that has been the standard treatment for patients with osteoarthritis, avascular necrosis, and/or fracture within the hip joint. In THA, both the acetabulum and the femoral head are replaced, and three components are required: A stem and a spherical head that replaces the femoral head, and a hemispherical cup with an inner liner to replace the acetabulum. While fundamental concept of hip arthroplasty has changed little since its appearance in medicine, the implants have experienced numerous changes in terms of material and design [1]. During the early stages of development, the THA implant had a metal-on-metal (MOM) bearing combination. All components were made cobalt-chrome alloy and bone cement was used to fixate the implant to the bone. The implant head was also similar in size as the anatomical head, giving the hip a natural physiological range of motion (ROM). When it was revealed that MOM produced high frictional torque, metal-on-polymer became the popular bearing combination choice. It soon became evident that debris from the plastic liner due to volumetric wear led to osteolysis and causing the implant to loosen. Thus, the implant head size was reduced to decrease the wear, which also decreased the ROM of the hip, limiting the patient’s mobility. The next fifty years saw the introduction of two more bearing combinations (ceramic-on-polymer and ceramic-on-ceramic), though much of the implant designs and the small head size remained unchanged. Presently, hip implants are available in all bearing combinations and in various shapes and sizes. THA implants with large head size are also becoming popular, as researches have shown that with larger head sizes, lubrication regime changes from boundary lubrication to fluid-film lubrication [2]. New researches in materials have also led to bearings having very low frictional coefficients. In addition, porous coat-
ings around the stem have led to the development of cementless implants, providing stronger bone fixation than using bone cement.

However, there are still risks to hip arthroplasty and thousands of revision surgery is conducted each year. The main indications for surgery that concerns the implant are aseptic loosening, dislocation, and the wear of acetabular component [3]. The main risk factors are can be categorized as being mechanical, biological, or biomechanical. Mechanical risk factors include incorrect determination of implant size, position, and orientation. As mentioned earlier, using a smaller implant head size decreases the ROM of the hip and increases the risk of the implant impinging with the cup, leading to dislocation [4,5]. Biological risk factors are derived from improper choice of implant type. With implants using bearing combinations of a polymer, the wear particles are associated with osteolysis, causing aseptic loosening of the implant. With MOM implants, the release of metal ions has been linked to metallosis. In addition, the size of head has been known to coincide with volumetric wear, with increasing head size leading to greater wear [6]. Both mechanical and biological risks have been heavily discussed in literature, and with proper clinical assessment and pre-surgical planning, the occurrence of these risks could be minimized. However, biomechanical risk factors are based on the remodeling of the bone, or the biological response due to mechanical change. Stress shielding is one factor in which the body load is shifted from the femur to the implant, causing osteopenia [7-11]. Such condition can cause aseptic loosening due to instability in fixation, or cause sudden fatal damage to the femur, such as fracture. In order to clinically assess biomechanical risks from an engineering perspective, researchers have focused on the bone adaptation theory [12-18].

The first bone adaptation theory, known as “Wolff’s Law” suggests that the bone adapts to changes in stress and tries to minimize load. Wolff also illustrated his version of principal stress projections and postulated the “Trajectorial Theory”, in which he noted that cancellous bone architecture is formed of a network of perpendicular intersections [19]. While Wolff’s Law has remained as the philosophy of bone remodeling, the Trajectorial Theory has been dismissed by modern research, as it has been found that the cancellous architecture is non-orthogonal, and its orientation is governed clearly by loading [20].

Finite element analysis (FEA) has frequently been used to simulate physiology of the femur, using patient-specific three-dimensional (3D) models made from computed tomography (CT) scan and inhomogeneous material properties calculated from the Hounsfield unit (HU) of the CT scan [21]. The use of FEA has allowed researchers to examine stresses and strains and to conduct risk assessments. Recently, the push for realism has introduced the use of telemetry devices to determine hip contact force in real time. Combining the data with musculoskeletal modeling has allowed researchers to mimic realistic physiological loading conditions [22-25]. Numerical and computational bone adaptation theory has also been suggested, following three basic concepts: Alteration in bone architecture due to mechanical stimulus, calculation of updated material property, and calculation of new stress and strain fields from updated material properties [26-30]. Computationally derived principal stress projections have also been evaluated with trabeculae structure of the femur with success [31,32].

Despite of the advancements in materials and designs, hip implants continue to cause complications. The National Joint Registry (NJR) for England and Wales, which has a large population and high rates of coverage, have recently revealed that the revision rate for MOM implants, specifically HRA implants, was much higher than other bearing combinations [33,34]. The findings have led to government health agencies in England and the United States to release alerts on the use of particular hip implants. Furthermore, within the past 10 years, major implant companies have recalled their implants. While researches concerning implant design have been conducted, most have been based on minimizing mechanical and biological risks. Patient-specific implants have also been simulated; however, the advantages have been minor compared to the cost and time to manufacture such implants [35-39]. Furthermore, long-term safety has not been addressed, which is a key factor for femur and implant survival, as well as the quality of life for the patient. Ideally, there should be minimal differences between the biomechanics of an intact femur and that of a femur with implant. Any alterations in loading will affect the stress and strain distribution, which will cause respective changes in the trabecular structure and henceforth the bone density. Thus, the primary design criteria of an implant must be based on minimizing biomechanical risks, followed by the minimization of mechanical and biological risks. In order to assess the effectiveness and safety of the implant design, it is necessary to first replicate the biomechanics of the femur, test under realistic physiological conditions, followed by bone remodeling simulation to predict long-term outcome. To the best of our knowledge, the combination of the three works has not yet been reported in literature.

The objectives of this study were to realistically simulate the physiological condition of the femur, to investigate the effects of an implant in the femur, and to utilize the obtained results for optimization of implant designs.

**Finite Element Modeling**

**3D models**

CT scans (512 x 512, 1 mm slices) from a male 54
ing environment as shown Figure 4. All models were meshed with linear unstructured tetrahedral mesh.

**Material properties**

Material properties of the femur were derived from the ash density extracted from the HU of the CT scans using the following formula:

\[
\text{Density} \left( \frac{g}{cm^2} \right) = \rho \left( \frac{HU}{\text{cm}^3} \right) + 1.4246 \times \frac{0.001}{0.0580} (H.U. > -1) \\
\text{Density} \left( \frac{g}{cm^2} \right) = 0 (H.U. \leq -1)
\]

The Young’s modulus and the yield stresses were calculated from the ash density as proposed by Keyak, et al. [21]. The Poisson’s ratio was set to 0.3. For the THA implant, titanium alloy was assigned to the stem with
the Young’s modulus of 114 GPa and the Poisson’s ratio of 0.34, and alumina to the head with the Young’s modulus of 370 GPa and the Poisson’s ratio of 0.32.

**Boundary conditions**

Simplified maximum walking (Table 1) contact forces determined by Heller, et al. were applied to the models [40]. Each % body weight (BW) was configured with the patient’s BW. Modifications were made on the locations of the origin and insertion of the muscle, as well as the distributions, for a realistic anatomical representation. Simplified abductor muscles were expanded to include gluteus medius, gluteus minimus, and gluteus maximum to the correct anatomical position and distribution as shown in Figure 5. The porous coating on the upper half of the implant was assumed to be fully bonded with the bone as expressed in Figure 6. Non-porous areas were assumed to have a friction coefficient of 0.2. Fixed constraint was applied to the distal femur.

**Bone adaptation algorithm**

Bone adaptation algorithm proposed by Huiskes, et al. was used in this experiment [30]. In the theoretical formulation, the rate of remodeling as the change of Young’s modulus, \( \frac{dE}{dt} \), was correlated with the strain energy density, \( U \), as follows:

\[
\frac{dE}{dt} = C (U - U_n)
\]

(3)

where \( C \) and \( U_n \) are the remodeling constant and the site-specific homeostatic equilibrium strain energy density, respectively. In the present analysis, \( C \) and \( U_n \) were set at \( 1.2 \times 10^5 \) and \( 0.011 \text{ MJ/m}^3 \), respectively.

**Results**

**Principal stress projections of intact model**

Preliminary principal stress projections predicted by FEA are shown in Figure 7. It was found that a distinct hypodense structure seen from the top of the femoral head tracing downwards to the calcar femorale of the femur on the CT image was represented as the minimum principal stress (red) on the FEA result. The epiphyseal line can also be seen in the CT scan, near the center of the femoral head. This is traceable by the maximum principal stress (blue). With the FEA result, it is also possible to view the five trabeculae groups: Principal tensile and compressive group (dashed), secondary tensile and compressive group (dotted), and the greater trochanter group. In the transverse plane shown in Figure 7b, it is possible to see both the epiphyseal line and the calcar femorale. With the coronal plane, principal stress projections can be drawn simply from the outer symmetry, as illustrated by Wolff. However, with
Effects of head size and stem length are shown in Figure 9 and Figure 10, respectively. The stress projections of $\Phi 34$ mm and $\Phi 40$ mm head are also similar to the intact bone; however, notable differences were seen with the $\Phi 48$ mm head implant; the calcar femorale region remained to be completely in compressive loading and much of the diaphysis has remained identical to the intact bone model shown in Figure 8. With regard to stem size, varying the length did not result in significant dif-
ferences as expressed in Figure 10. The loading region does appear to change in proportion to the stem length.

Distribution of equivalent stress in THA and RHA models

To assess the post-operative safety of the implant, the equivalent stress distribution of each model was investigated and compared to the intact bone model. Drucker-Prager yield criterion was chosen as bone is a brittle material and the compressive strength is higher than the tensile strength [41,42]. Equivalent stress distribution of the THA model reveals that the proximal lateral section experiences high stress, while the distal lateral section experiences low stress as shown in Figure 11. However, the stress increases around the implant tip. Proximal medial region, around the porous coating of the implant, also experiences high stress, although it appears to decrease distally. With increasing head size, the high stress in the diaphysis region seen in the standard THA model becomes absent as shown in Figure 12. The stresses in the greater trochanter also appear to fade. With ø48 mm head, the stress distribution closely resembles that of the intact bone. Furthermore, stress around the implant stem is not evident. Similar to the previous stress projection result, equivalent stress distribution did not differ to the THA stem despite differences in stem length as shown in Figure 13.

Bone remodeling behavior

Preliminary inspection is important to inspect the changes in the physiology of post-operative femur, but so far, only the mechanical aspects have been considered. In order to assess post-operative conditions and long-term outcomes, bone remodeling simulation is required. Bone remodeling was conducted on the standard implant with two main implants, THA implant with ø48 mm head size, and THA implant with 50% stem length. The changes of principal stress projections at different times are shown in Figure 14 for the standard model, Figure 15 for the model with ø48 mm head size, and Figure 16 for the model with 50% stem length. Thus, all implant models were remodeled until steady state was reached. Significant changes occur in the femoral head, as the disappearance of trabeculae groups causes formations of an unnatural trabeculae group as shown in Figure 17. The significant change with the THA implant model is the restoration of the medial and lateral projections, as well as the projections at the calcare femorale, which has changed back to compressive projections as shown in Figure 14. Collections of projections still remain along the surface of the implant and stem tip and continues until the remodeling reaches steady state. A clear area without projections also appears beneath the greater trochanter. In Figure 15 and Figure 16, the key difference is the absence of stress projections around the implant tip.

Bone mineral density

Bone mineral density (BMD) was analyzed to link projections to trabeculae structure and the results are shown in Figure 17. For implant models, this was calculated at t5 corresponding to the steady state stage. BMD of the intact bone was directly derived from the
ed implant, on the other hand, does not show signs of increased BMD.

**Discussion**

THA implants showed significant changes in the trabeculae structure in the preliminary experiment, apart from the ø48 mm head implant, which was able to maintain the characteristics of the diaphysis. When the Drrucker-Prager equivalent stress was inspected, THA models revealed extremely high stress areas around the proximal region. Again, the distributions of the larger head-sized implant were akin to the intact bone model.

While bone remodeling simulation has revealed that the diaphysis returns to its original state, the lat-
eral proximal region, below the greater trochanter, and the tip of the implant stem, remains to be an issue. This finding was also reflected with the BMD analysis, where increased bone density was found in identical locations. Such characteristics where two highly densified areas separated by low density region could lead to peri-prosthetic fracture. These findings were found for the standard THA model and the shortened THA model but were not consistent with the larger head implant model. In all cases, the implant closely matched the results of the intact bone model.

The design concept behind HRA is justifiable as a larger head size increases the ROM of the joint. However, long-term computational assessments and BMD results have shown that it does not fare well when compared THA implants. THA implants, despite of differences from the intact bone, does maintain BMD throughout the diaphysis. Shorter stem length has also showed similar results with the standard THA. Furthermore, a larger head has shown to be superior to the standard THA. From a medical standpoint, decreasing the stem size correlates with conservation of bone mass, and increasing head size correlates with increased ROM.

**Conclusions**

A novel process to simulate long-term biomechanics of femur with THA implant has been proposed. FEA has provided to be an integral tool to realistically model the biomechanics of the femur, with the use of realistic physiological loading conditions. Computational mod-
eling of bone adaptation has also predicted the long-term physiological outcome of a femur with implant and conducting risk assessments have revealed possible fracture areas due to long-term remodeling. Using this process, implant designers can investigate the femur's biomechanics, and long-term assessments can estimate when post-operative follow-up should be performed before serious damages occur. The research has closely achieved clinical results with engineering methodology. It has also shown that mechanical assessment is not enough to effectively evaluate the implant. Biomechanical assessment must be conducted to fully establish the safety of a design.
