Abstract
Adenocarcinoma of prostate is the most common cancer affecting men in United States. The most common sites of prostate cancer metastasis are to bone and pelvic lymph nodes. Brain metastases are rare and reported in less than 1% of prostate cancer patients. Among the patients with brain metastasis, most of them had concurrent systemic disease involvement, such as: bone, lymph node, liver and/or lung metastasis [1,2]. We report a case of patient with low risk prostate cancer, stage IV B, with well controlled systemic disease and developed brain metastasis.

Keywords
Brain metastases, Metastatic cancer, Prostate cancer, Stereotactic radiosurgery, Radiotherapy

Case Presentation
An 83-year-old Caucasian male was initially diagnosed with prostate adenocarcinoma involving left base, left mid and left apex, T1C and Gleason score 6 (3 + 3) in 2008, His Prostate-Specific Antigen (PSA) at time of diagnosis was 7.49 ng/mL. The patient underwent prostatectomy followed by adjuvant radiotherapy (73.8 Gy in 41 fractions) in February 2009. He was monitored with serial PSA after radiation treatment. In April of 2017, his PSA increased to 17 ng/mL. He underwent bone scan which showed metastatic disease to the frontal bone, multiple sternocostal joints and ribs. He was started on treatment with bicalutamide 50 mg daily for 1 month and 22.5 mg of Lupron IM. After that, Lupron was given based on testosterone levels (if testosterone level > 50 ng/dL, patient will get Lupron injection). Patient responded very well to the treatment and his PSA levels decreased to 0.2 ng/mL. In middle of 2018, patient’s PSA was slowly increasing and by November 2018, it was 2.4 ng/mL. His testosterone levels were below 50 ng/dL and was diagnosed with metastatic castrate resistant prostate cancer (mCRPC). Scans showed sclerosis of bone metastasis without new bone involvement or lymph node metastasis. Treatment with enzalutamide was recommended but not started because of high out-of-pocket expenses; therefore, he was continued with Lupron.

In January 2019, he complained of low energy and increasing sleepiness, otherwise, no neurological deficits. The Magnetic Resonance Imaging (MRI) of his brain showed a solitary lesion of 4.4 × 3.6 × 4.8 cm in the right frontal cortex with surrounding edema and leftward midline shift (Figure 1A). Computed tomography (CT) scan of chest/abdomen/pelvis and bone scan showed stable sclerotic low volume metastatic disease in bones compared to his previous scans. Patient underwent right-sided craniotomy and resection of the mass. Final pathology was consistent with adenocarcinoma, prostate origin. His mental status and memory improved after surgery. Three months later, he had underwent stereotactic radiation therapy to the surgical cavity with 55.5 Gy in right frontal brain cavity. Repeated MRI of the brain showed removal of the tumor and effect...
of all central nervous system (CNS) tumors [3,4]. The median survival of patients with metastatic brain lesions is approximately 7-16 months from diagnosis [5]. While cutaneous melanoma and carcinomas of lung, breast, kidney, and colon commonly metastasize in the brain [6,7]; brain metastases from prostate cancer is very infrequent and poorly understood. Less than 1% of patients with prostate cancer were reported to have brain metastasis [8]. Among that, about five percent of the cases were diagnosed in postmortem examination [9]. Its rarity can be explained by earlier detection, indolent nature and effective treatments, preventing extraprostatic spread. Others possible explanation is that brain parenchyma is resistant to the establishment of metastatic foci by prostate adenocarcinoma cells [10].

Discussion

Metastatic brain lesions account for more than 50% of postoperative stereotactic radiation (Figure 1B). Patient’s testosterone levels remained castrate and did not require further Lupron treatment.

The patient felt general decline in his performance status and wanted to focus on quality of life. He was referred to hospice in September 2019. In March 2020, patient was feeling better, he rescinded hospice and presented to oncology clinic for follow-up. His PSA level was 0.5 ng/mL (Figure 2) with no evidence of systemic progression on CT and bone scans. Figure 3 illustrated the timeline of the events since his initial diagnosis of prostate cancer.

Figure 1: Magnetic Resonance Imaging of the brain at the axial plane. A) The hyperintense area (yellow arrow) showed lobulated, heterogeneously enhancing mass of 4.4 × 3.6 × 4.8 cm within the right frontal lobe with surrounding edema, effacement of the right frontal horn, and a 1.6 cm leftward midline shift, B) The T1 black hole (yellow arrow) showed removal of the tumor and effect of postoperative stereotactic radiation.

were non-focal and could be asymptomatic [13], and often presented with cognitive changes and generalized headache. In our case, the patient presented with minimal neurological symptoms with generalized fatigue and sleepiness as clinical manifestations of brain metastasis eleven years after diagnosis of prostate cancer. MRI has been the gold standard to evaluate brain tumors. However, it remains a challenge to distinguish the lesions of brain metastasis from prostate cancer vs. from other types of cancers. It is due to its high variety of imaging presentation with no specific characteristics [2].

While surgical intervention has been playing a role in palliative treatment for patients with brain metastasis [14]; it is uncommonly performed due to the presence of widespread, systemic disease, low performance status, and short life expectancy. However, it has more benefit in patients with accessible, single brain lesion with good functional status. Meanwhile, stereotactic radiosurgery (SRS) is an established non-invasive ablative

therapy widely adopted for unresected brain metastasis or as adjuvant therapy. In previous years, adjuvant Whole Brain Radiation Therapy (WBRT) along with surgical resection or with SRS has shown to significantly reduce the risk of recurrence from 60% to approximately 30% [15]. Hence, the combination of surgery and WBRT has been the standard of care for solitary brain metastasis. Despite, the concern of long-term neurotoxicity and quality of life limit the use of adjuvant WBRT [16]. Therefore, the use of high dose radiation to postoperative surgical bed with SRS is common in clinical practice [17], which was shown to have 79% local control rate at 12 months compared to 54% with observation only vs. with WBRT (80-90%) [18]. In our patient, surgery and postoperative SRS to tumor bed were given and resulted in favorable outcome with good neurocognitive function thereafter.

The prognosis of prostate cancer patients with brain metastasis is very poor with reported median survival time ranging from 1 to 7.7 months [19,20]. It could be due to the majority of prostate cancer with brain metastasis also had concurrent distant metastasis [1]. In addition, the studied patients were high risk group with Gleason score ≥ 7. Despite, there are some published case reports indicated better prognosis with more than 2 years survival after treatment [21,22]. Simultaneously, our patient had low-risk prostate cancer who is doing well after 16 months since diagnosis and treatment of brain metastasis and rescinded hospice. It can likely be explained by his well-controlled systemic disease and solitary brain metastasis which was optimally treated with no recurrence.

Conclusion

Prostate cancer with metastasis to brain is very rare, associated with widespread systemic disease and low median survival. We report a case of low-risk prostate cancer and well-controlled systemic disease presenting with solitary brain metastasis eleven years later, which emphasizes the importance of continued surveillance even in low-risk patients. Moreover, aggressive treatment of the metastatic site with tumor resection and adjuvant stereotactic radiation to the surgical bed deemed optimal in the management of this patient and associated with better outcome.
