Abstract

Introduction: Over 60 years ago Caplan’s syndrome was described in the coal miners of South Wales (UK). Higher rates are seen in mining populations globally, particularly in kaolin workers. We describe Caplan’s syndrome in a kaolin worker associated with a raised urinary cadmium level.

Case report: A 65-year-old Cornish kaolin worker with life limiting nodular erosive Rheumatoid Arthritis (RA) developed extra-articular manifestations including pulmonary nodules suggestive of Caplan’s syndrome. Urinary cadmium was raised at 0.66 μmol/mol creatinine (UK male median 0.16 μmol/mol creatinine), 20 years post-industrial exposure cessation.

Discussion: Caplan’s syndrome prevalence in kaolin workers is the highest of any occupation ever reported. Extremely elevated cadmium levels of 11.2–15.9 mg/kg have been observed in kaolin, fifty-fold higher than those reported in coal. Coal contains variable amounts of clays and minerals such as kaolinite, which determine cadmium content.

We suggest that the kaolinite mineral capacity for adsorption of heavy metals, in particular cadmium, explains the scale and pattern of Caplan’s syndrome prevalence seen in global mining populations, and further explains the pronounced interaction seen in sequential dust exposure and cadmium laden cigarette smoke.

Introduction

Caplan’s syndrome, first described in 1953 amongst Welsh coal miners, classically occurs in individuals with both Rheumatoid Arthritis (RA) and coal dust exposure [1]. It is characterised by development of pulmonary nodules 0.5–5 cm throughout the lung field, distinct from silicosis [1,2]. This is of contemporary interest as lung inflammation is now considered to be an important site of RA initiation.

Regional differences in the prevalence of Caplan’s syndrome have been reported in pneumoconiosis patients, from 0.4–1.5% [2]. This raises an intriguing question; what is the specific component of coal dust responsible for the development of rheumatoid pulmonary nodules and the development of RA?

We hypothesise that kaolinite mineral adsorption predisposes to increased pulmonary cadmium levels as a result of both a direct cadmium load and enhanced pulmonary cadmium adsorption from cigarette smoke.

We describe a kaolin worker with Caplan’s syndrome and elevated urinary cadmium levels and discuss the relevant literature to support the hypothesis that cadmium can trigger rheumatoid pulmonary nodule formation and RA development.
Discussion

A diagnosis of Caplan’s syndrome is evident by a diagnosis of RA, occupational dust exposure and radiological evidence of multiple pulmonary nodules. Kaolin workers are at high risk of Caplan’s syndrome [4]. Kaolinitis is a complication of kaolin exposure, distinct from silicosis. Caplan’s syndrome prevalence in kaolinitis is over seven times higher than originally reported in pneumoconiosis claimants (3% vs. 0.4%) [2, 4].

Inhalation of fine kaolin dust can occur, particularly in drying phases of production. An experienced Cornish pathologist described being able to remove kaolin from the lungs of workers at post mortem "with a tablespoon" (Figure 2). Kaolin related employment in Cornwall declined to 900 people in 2014. However, 52/700 (7.4%) RA males under follow up at the Royal Cornwall Hospital have worked for > 1 year in the kaolin industry, 12 times more than expected based on current occupational data. Likewise, in Staffordshire (UK) underground coal miners have been demonstrated to have a significantly increased risk of RA development (odds ratio 8.47, 95% CI 2.59-27.66) [5].

Kaolin and coal dusts share a predisposition for a common contaminant: Elemental cadmium. Cadmium content of coal varies, with a strong association noted between the kaolinite mineralisation of coal and cadmium content [6]. Far higher cadmium levels have been observed in West African kaolin (11.2-15.9 mg/kg), suggestive of local contamination by adsorption [7]. Mineral kaolinite is formed by geological feldspar decomposition, comprising a \( (\text{Si}_2\text{O}_5)^2+ \) tetrahedral layer and an \( (\text{Al}_2\text{O}_3\text{H})_4^{1+} \) octahedral layer bonded together by shared oxygen atoms between adjacent silicon and aluminium atoms [8]. Substitution of \( \text{Si}^{4+} \) by \( \text{Al}^{3+} \) gives rise to “permanent” active sites for adsorption in surface tetrahedral sheets, with “variable” pH-dependent adsorption.

Case Report

A 65-year-old male from Cornwall, UK, developed nodular RA aged 32. Rose-Waaler testing at diagnosis was 1/2048 and a forefoot arthroplasty was undertaken within a year. He had worked for 16 years in kaolin drying refineries in Cornwall, UK, with consequent dust inhalation. He accumulated 20 pack years of cigarette smoking to age 30 years.

Aged 55 he presented with a Pulmonary Embolus (PE), confirmed on CT Pulmonary Angiography (CTPA). Further CTPA imaging excluded recurrent PE as a cause of escalating shortness of breath symptoms. Radiology review of sequential CT chest imaging (2006-2008) demonstrated multiple pulmonary nodules consistent with Caplan’s syndrome (Figure 1). Subsequent development of rheumatoid vasculitis has been treated effectively with rituximab.

Contemporary serology levels demonstrated a rheumatoid factor of 481.7 iu/ml (0-10 normal range) and an anti-cyclic citrullinated peptide of > 500 u/ml (0 - 17 normal range).

Given our interest in the role of occupation in RA development with reference to cadmium inhalation, a urinary cadmium level was undertaken, (0.66 μmol/mol creatinine, UK median 0.17, 95th centile 0.57) [3]. We suggest occupational kaolin dust inhalation has resulted in the significantly raised urinary cadmium level reported here.

Figure 1: Horizontal CT single slice. Black frames highlight multiple well circumscribed > 0.5 cm Caplan’s nodules throughout lower lobes bilaterally, more marked on left than right.
men asphalters: Smokers demonstrated a six-fold increase in serum cadmium compared to either non-smoking colleagues or control smokers [12]. Further evidence is seen in an animal model. Rat lung instilled with cadmium-containing silica nanoparticles demonstrated greater expression of pro-inflammatory cytokines and granuloma formation than lung exposed to cadmium alone or silica nanoparticles alone [13]. All exposures demonstrated parenchymal inflammation, granuloma formation, cytokine expression and stromal fibrogenic reactions.

Cadmium contamination of coal is a long-term health concern. Toxic blood cadmium levels have been demonstrated in 85% of children living in a Turkish coal mining area [14] (mean serum cadmium 13.1 μg/L). Recent South Korean literature reports RA prevalence odds ratio increasing by 1.62 per 1 μg/L increase in serum cadmium [15].

We postulate that kaolin dust in this ex-smoker’s lungs adsorbed cadmium from cigarette smoke, increasing intrapulmonary cadmium concentration, stimulating inflammation and disease development.

This case highlights the importance of occupational dust exposure in RA, and further studies are underway to determine if kaolin workers have high levels of bodily cadmium and an increased RA risk. We highlight the process of adsorption as an overlooked factor, explaining the interaction of silica and non-silica based dust and cigarette smoking seen in RA.

Acknowledgements

We would like to thank Cornwall Arthritis Trust for their financial support of this work.

Funding

Ongoing funding for research into occupational exposures in rheumatoid arthritis in Cornwall is provided by Cornwall Arthritis Trust, a registered charity. No specific funding for this case report was provided.

Competing Interests

None.
